Abstract

Costs or benefits which accumulate for individuals over time are of interest in many life history processes. Familiar examples include costs of health care for persons with chronic medical conditions, the payments to insured persons during periods of disability, and quality of life which is sometimes used in the evaluation of treatments in terminally ill patients. For convenience, here we use the term costs to refer to cost or other cumulative measures. Two important scenarios are (i) where costs are associated with the occurrence of certain events, so that total cost accumulates as a step function, and (ii) where individuals may move between various states over time, with cost accumulating at a constant rate determined by the state occupied. In both cases, there is frequently a random variable T that represents the duration of the process generating the costs. Here we consider estimation of the mean cumulative cost over a period of interest using methods based upon marginal features of the cost process and intensity based models. Robustness to adaptive censoring is discussed in the context of the multi-state methods. Data from a quality of life study of breast cancer patients are used to illustrate the methods.

Keywords: Adaptive censoring, cumulative processes, marginal methods, multi-state processes, quality adjusted life-years, prevalence function.

1 Introduction

Costs or benefits that accumulate over time for individuals are of interest in many life history processes. Familiar examples include the cost of health care for persons with chronic medical conditions, the payments to insured persons during periods of disability, and cumulative quality of life measures which are sometimes used in the evaluation of treatments for terminally ill patients. Costs or benefits may be
Cumulative processes related to event histories

multivariate and may accrue for a variety of reasons. For example, in studies of persons with chronic obstructive pulmonary disease (e.g. Torrance et al., 1999) costs were incurred by prescription of prophylactic or therapeutic medications, by hospitalizations, by time off work, and so on.

For convenience we will often use the term costs to refer to cost or other cumulative measures such as utility, profit, or quality of life, and let $C(t)$ denote a cumulative (univariate) cost for an individual over the time period $(0,t)$. There is typically also a random variable $T$ that represents the duration of the cumulative process, so the objects of interest are $T$ and $\{C(t), 0 \leq t \leq T\}$. Simple methods for the analysis of cumulative cost (e.g. Lin et al., 1997; Zhao and Tsiatis, 1997) have focussed directly on them, or in some cases, just on the total lifetime cost, $C(T)$. However, a more informative approach is to consider the underlying event processes that generate costs, along with the costs themselves. For example, in a breast cancer trial (Gelber et al. 1995) discussed later in the paper, different utilities were assigned for periods in which patients were (i) subject to toxic effects of treatment, (ii) toxicity-free and relapse-free, and (iii) in a state of relapse. Cumulative utility was then used to define a quality of life measure, so that $C(T)$ can be thought of as a “quality-adjusted” lifetime.

Advantages of analyzing and modeling the event processes that generate costs include increased understanding; the ability to deal with observation schemes involving censoring, intermittent observation, or truncation; methods for predicting costs; a convenient separation of the underlying event process from costs which may be subjective, or subject to differing interpretations. The purpose of this paper is to review models on which analysis of cumulative costs can be based, and to discuss efficiency and robustness properties associated with these approaches. An analysis of data on the treatment of breast cancer patients (Gelber et al. 1995) will be used for illustration.

We now set some general notation and describe two frameworks that have been used to study cumulative processes.

The first framework assumes that for each individual $i$ in a study there is a cumulative cost (or quality) process $\{C_i(t), t \geq 0\}$, and a time $T_i$ at which the process terminates. For example, in a cost of treatment study $T_i$ would represent the duration of the treatment period for the individual. In studies of the utilization of health care resources among patients with terminal medical conditions, $T_i$ would represent the time of death. In many studies the value of $T_i$ may be right-censored at some censoring time $\tau_i$, in which case the cost process is unobserved for $t > \tau_i$. Considerable previous work has focussed on nonparametric estimation of the distribution of “total lifetime cost” $C_i = C(T_i)$, or just on $E(C_i)$; see for example Lin et al. (1997), Zhao and Tsiatis (1997), Bang and Tsiatis (2000), Ghosh and Lin (2000), and Strawderman (2000). In most realistic situations $T_i$ is not independent of the cost process; more specifically, if $\bar{C}_i(t) = \{C_i(u), 0 \leq u < t\}$ is the cost history to time $t$, then the termination time hazard function,

$$\lim_{\Delta t \to 0} \frac{Pr(T_i < t + \Delta t | T_i \geq t, \bar{C}_i(t))}{\Delta t}, \quad (1.1)$$
depends on $C_i(t)$. This implies that, even if the censoring time $\tau_i$ and $(T_i, C_i(T_i))$ are independent, the censoring value $C_i = C(\tau_i)$ and the total lifetime cost $C_i = C(T_i)$ are not in general independent.

The second framework we discuss models the underlying multi-state process driving the costs. Suppose that at time $t$ an individual occupies one of $K$ life states $1, \ldots, K$. It is assumed that all individuals begin in state 1 at $t = 0$, that states $1, \ldots, K - 1$ are transient and that state $K$ is an absorbing state. Letting $Y(t)$ represent the state occupied by an individual at time $t$, we assume that there is a cost rate function $V[Y(u), t]$ that determines the incremental cost over the short interval $(t, t + dt)$. The total cumulative cost up to time $t$ is then

$$C(t) = \int_0^t V[Y(u), u]du.$$  \hspace{1cm} (1.2)

The process terminates upon entry to state $K$, which occurs at time $T$, so that $V[K, u] = 0$ for all $u > 0$.

Given $(Y(u), u)$, the cost rate function $V[Y(u), u]$ may in general be random, but we restrict consideration to cases where

$$V[Y(u), u] = v_j(u) \quad \text{if} \quad Y(u) = j,$$  \hspace{1cm} (1.3)

where $v_j(u)$ is a known (deterministic) function, $j = 1, 2, \ldots, K$. In this case (1.2) gives

$$C(t) = \sum_{j=1}^{K-1} \int_0^t v_j(u)I[Y(u) = j]du$$  \hspace{1cm} (1.4)

and

$$E[C(t)] = \sum_{j=1}^{K-1} \int_0^t v_j(u)p_j(u)du,$$  \hspace{1cm} (1.5)

where

$$p_j(u) = Pr[Y(u) = j], \quad j = 1, \ldots, K,$$  \hspace{1cm} (1.6)

are prevalence functions. Gelber et al. (1995), Glasziou et al. (1990) and others have considered the case where $v_j(u) = v_j$ in connection with quality of life.

Note that in this framework $C(T) = C(\infty)$, and process termination is conveniently handled within the multi-state model. However, assumptions about the process \{Y(t), t \geq 0\} are needed. In a completely general setting transition intensities might depend on prior cost history, but in the case of deterministic cost rate functions (1.3) we have

$$Pr[Y(t+\Delta t) = j|Y(t), \bar{C}(t)] = Pr[Y(t+\Delta t) = j|Y(t)]$$  \hspace{1cm} (1.7)

so we merely need to model the multi-state process.

The remainder of the paper is as follows. Section 2 reviews strategies for estimation of cost distributions and addresses the multi-state framework in more detail. Methods
Cumulative processes related to event histories

Based on full models are compared with those based on recently proposed robust nonparametric estimates of prevalence functions \( p_j(t) \). Section 3 examines the various methods in the context of quality of life assessments in an IBCSG Breast Cancer Trial (e.g. Gelber et al. 1995). Section 4 presents conclusions and discusses additional problems.

2 Strategies for estimation

2.1 Marginal methods

Suppose interest lies in the distribution of \( C = C(T) \). Furthermore assume \( \tau \) is independent of \( (T, \overline{C}(T)) \) with corresponding survivor function \( K(t) = P(\tau > t) \). In this setting we observe \( X = T \wedge \tau, \Delta = I(T \leq \tau) \) and \( \overline{C}(X) = \{C(u), \ 0 \leq u < X \} \) which we denote as \( (X, \Delta, \overline{C}(X)) \). If \( n \) individuals are under observation and their responses are independently distributed, then we observe \( n \) independent replicates \( \{(X_i, \Delta_i, \overline{C}_i(X_i)), i = 1, \ldots, n\} \).

Glasziou et al. (1990) point out that even when \( \tau \) is independent of \( (T, C) \), the \( C \)-censoring value, \( C^* = C(\tau) \), and \( C \) are correlated. As a result, the assumption of independent censoring for \( C \) is violated, and

\[
\lim_{\Delta c \downarrow 0} \frac{Pr\{C < c + \Delta c | C \geq c, C^* \geq c\}}{\Delta c} \neq \lim_{\Delta c \downarrow 0} \frac{Pr\{C < c + \Delta c | C \geq c\}}{\Delta c}.
\]

Zhao and Tsiatis (1997, 1999), Bang and Tsiatis (2000), and others suggest the use of “inverse probability of censoring-weighted” estimating equations (e.g. Robins and Rotnitzky, 1995) for estimation of the survivor function \( Pr(C \geq c) \) to adjust for the dependent censoring induced by \( \tau \). Specifically they propose the estimate

\[
\hat{Pr}(C \geq c) = \frac{1}{n} \sum_{i=1}^{n} \frac{\Delta_i}{K(T_i)} I(C_i \geq c)
\]

where \( \hat{K}(t) \) is a consistent estimate of the censoring time survivor function.

The expected cost up to time \( t \),

\[
\mu(t) = E\{C(T \wedge t)\}
\]

is often of interest, as is the expected lifetime cost \( E(C) = \mu(\infty) \). These can be estimated using the fact that

\[
\mu(t) = \int_{0}^{\infty} Pr[C(T \wedge t) > c] dc.
\]

Cook and Lawless (1997), Lin et al. (1997) and Ghosh and Lin (2000) discuss alternative estimators based on the fact that

\[
\mu(t) = \int_{0}^{t} S(u) dM(u),
\]
where $S(u) = Pr(T_i \geq u)$ and $dM(u) = E\{dC_i(u) | T_i \geq u\}$. We can estimate $S(u)$ with an ordinary Kaplan-Meier estimate, and $dM(u)$ as

$$d\hat{M}(u) = \sum_{i=1}^{n} I(X_i \geq u) dC_i(u) / \sum_{i=1}^{n} I(X_i \geq u). \tag{2.5}$$

Strawderman (2000) discusses and compares (2.5) and estimators based on (2.1) and (2.3).

The estimators above were developed under the assumption that censoring times $\tau_i$ are independent of $(T_i, C(T_i))$, $i = 1, \ldots, n$. This is sometimes violated, as we discuss below. The next two sections deal with methods based on multi-state models and how to deal with non-independent censoring.

### 2.2 Methods based on multi-state models

We consider methods based on specific models for multi-state processes below. First, we describe an alternative approach based on marginal Kaplan-Meier estimates which was suggested by Glasziou et al. (1990) and developed more formally by Pepe et al. (1991).

Let $T_j^{(\ell)}$ and $W_j^{(\ell)}$ denote the times of the $\ell$'th entry and exit from state $j$, respectively. The prevalence functions can then be written for $j = 1, \ldots, K - 1$ as

$$p_j(t) = \sum_{\ell=1}^{\infty} \left[ Pr(T_j^{(\ell)} \leq t) - Pr(W_j^{(\ell)} \leq t) \right] \tag{2.6}$$

and the expected total time spent in state $j$ over the interval $(0, t)$ as

$$\mu_j(t) = \int_0^t p_j(u) du$$

$$= \sum_{\ell=1}^{\infty} \left[ E(W_j^{(\ell)} \wedge t) - E(T_j^{(\ell)} \wedge t) \right], \quad j = 1, \ldots, K - 1. \tag{2.7}$$

The example in Section 3 involves the progressive model shown in Figure 1. In this setting we let $T_k^{(1)} = T_k$, $k = 1, 2, \ldots, K$ and $W_k^{(1)} = W_k$, $k = 1, 2, \ldots, K - 1$ since each state can be visited only once, and note that $T_1 = 0$, $T_2 = W_1$, $T_3 = W_2$, and $T_4 = W_3$. Then (2.6) gives

$$p_j(t) = Pr(W_j \geq t) - Pr(W_{j-1} \geq t) = S_j(t) - S_{j-1}(t), \quad t > 0, \quad j = 1, 2, 3, \tag{2.8}$$

![Figure 1: A Progressive Model.](image-url)
where \( W_0 = 0 \). Assuming that censoring times \( \tau_i \) are independent of \( W_1, W_2, W_3 \), we can estimate the \( S_j \)'s with standard Kaplan-Meier estimates. Specifically, let \( N_{ij}(t) \) denote the counting process recording the number of transitions out of state \( j \) (and into state \( j+1 \)) by subject \( i \) up to time \( t \) and let \( \delta_{ij}(t) = I(t \leq \min(W_{ij}, \tau_i)) \) denote the “at risk” indicators for exit from state \( j \). Then if \( w_{ij} (\ell = 1, 2, \ldots, L_j) \) denote the distinct times of transitions from state \( j \) to state \( j+1 \) across all individuals, the Kaplan-Meier estimate for \( S_j(t) = Pr(W_j \geq t) \) is

\[
\hat{S}_j(t) = \prod_{w_{ij} \leq t} \left( 1 - \frac{dN_{ij}(w_{ij})}{\delta_{ij}(w_{ij})} \right), \tag{2.9}
\]

where dots indicate summation over \( i = 1, \ldots, n \) and \( dX(t) = X(t) - X(t-) \) for any right-continuous process.

The approach just described uses the progressive nature of the process in Figure 1, but is readily extendible to any other multi-state processes of the type considered here, through (2.7) and the use of Kaplan-Meier estimates for the survivor functions of the random variables \( T_j^{(t)} \) and \( W_j^{(t)} \). Pepe (1991), Pepe et al. (1991), and Couper and Pepe (1997) discuss specific types of processes, and variance and covariance estimates for the Kaplan-Meier estimates.

Prevalence functions can also be estimated by developing a full probabilistic model for the multi-state process. This can be done by specifying transition intensities, denoted here by

\[
\lambda_{kk'}(t|Y(t)) = \lim_{\Delta t \downarrow 0} \frac{P(Y(t + \Delta t) = k'|Y(t) = k)}{\Delta t}, \quad k \neq k'.
\]

Methods based on Markov models where \( \lambda_{kk'}(t|Y(t)) = \lambda_{kk'}(t) \) are well known, and nonparametric estimation of transition probabilities is given by the Aalen-Johansen estimates (Andersen et al. 1993, Section 4.4). Couper and Pepe (1997), Aalen et al. (2001) and Datta and Satten (2001) point out that the Aalen-Johansen estimator of the prevalence functions, while formally justified under a Markov assumption, in fact provides a consistent estimate of the state occupancy probabilities (prevalence functions) for non-Markov processes. To show this, Datta and Satten (2001) consider the “partially conditioned transition rate” (Pepe and Cai, 1993),

\[
\alpha_{kk'}(t) = \lim_{\Delta t \downarrow 0} \frac{P(Y(t + \Delta t) = k | Y(t) = k)}{\Delta t}, \quad k \neq k',
\]

with \( \alpha_{kk}(t) = -\sum_{k' \neq k} \alpha_{kk'}(t) \), as well as a corresponding integrated transition rate \( A_{kk'}(t) = \int_0^t \alpha_{kk'}(u)du \) with matrix form \( A(t) = \{A_{kk'}(t)\} \). The \( \alpha_{kk'}(t) \) are also the transition intensity functions for Markov models but not for non-Markov models. Let \( N_{kk'}(t) \) denote the cumulative number of transitions from state \( k \) to \( k' \) over \( (0,t] \) for subject \( i \) and \( N_{kk'}(t) = \sum_{u=1}^n I(t \leq \tau_i)N_{kk'}(t) \). Let \( Y_k(u) = I(Y_i(u^-) = k) \), and \( Y_k(u) = \sum_{t=1}^n I(u \leq \tau_i)Y_k(u) \). The Markov process estimator is the Nelson-Aalen estimate of
Akk′(t),
\[ \hat{A}_{kk'}(t) = \int_0^t I(Y_k(u) > 0) \frac{dN_{kk'}(u)}{Y_k(u)}. \]

Product integration gives the Aalen-Johansen estimate of the transition probability matrix over \((0, t)\) as
\[ \hat{P}(0, t) = \prod_{(0, t]} (I + d\hat{A}(u)). \]  
(2.10)

If \(p(0) = (p_1(0), \ldots, p_K(0))^t\) is the initial probability vector, then the prevalences (1.6) at time \(t\) are estimated as \(p(0)^t \hat{P}(0, t)\). The estimate (2.10) is not robust to departures from the Markov model, but Couper and Pepe (1997), Aalen et al. (2001), and Datta and Satten (2001) show that the estimates of the prevalence functions \(p_j(t)\) are robust to departures from the Markov model under the assumption that censoring times \(\tau_i\) are independent of the multi-state processes. Glidden (2002) discusses variance estimation for the \(\hat{p}_j(t)\)’s.

If there is no censoring until after time \(t\), then the Glasziou-Pepe estimates of \(p_j(t)\) based on (2.6) and the Markov (Aalen-Johansen) estimates based on (2.10) are identical and equal to the observed prevalences \(\sum_{i=1}^n I(Y_i(t) = j)/n\). Obtaining variance estimates for \(\hat{\mu}(t) = \sum_{j=1}^{K-1} \int_0^t v_j(u) \hat{p}_j(u) du\)  
(2.11)
in the general case is messy via delta method techniques (see Praestgaard 1991 for similar calculations) and bootstrap methods seem the best approach. We also note that the Cook-Lawless (1997) estimate of \(\mu(t)\) based on (2.4) and (2.5) uses, under (1.3),
\[ d\hat{M}(u) = \frac{\sum_{i=1}^n \sum_{j=1}^{K-1} v_j(u)I(X_i \geq u)I[Y_i(u) = j]du}{\sum_{i=1}^n I(X_i \geq u)} \]
\[ = \sum_{j=1}^{K-1} v_j(u) \left( \frac{\sum_{i=1}^n I(X_i \geq u)I[Y_i(u) = j]}{\sum_{i=1}^n I(X_i \geq u)} \right) du \]
and so differs from (2.11) by the use of an empirical prevalence estimate \(\hat{p}_j(u)\) instead of the Glasziou-Pepe or Aalen-Johansen estimates. It is identical to the other estimates when there is no censoring until after time \(t\), but might be expected to be less efficient with censored data.

The methods in this section assume that censoring is completely independent of the multi-state process. Thus, for example, if censoring were state-dependent, bias could occur. The next section discusses ways of dealing with this.
2.3 State-dependent censoring

The assumption of general independent censoring (e.g., Andersen et al. 1993, pp. 139-40; Kalbfleisch and Prentice 2002, pp. 194-5) implies that at any time the transition intensities for individuals that are under observation are representative of those in the population of interest at that time. This allows consistent estimation of hazard functions or state transition intensities. Thus, the transition probability matrix (2.10) and associated prevalence estimators are consistent when there is general independent censoring, provided the multi-state model is Markov. This means that censoring does not have to be fully independent of the multi-state process, but could be state-dependent. However, the Glasziou-Pepe estimators based on (2.8) and (2.9) are not valid under state-dependent censoring. To illustrate this, consider the estimate for \( S_3(t) \) in (2.8), which from (2.9), has jumps determined by

\[
dH_3(t) = \frac{dN_{34}(t)}{\delta_3(t)} = \frac{dN_{34}(t)}{Y_{1}(t) + Y_{2}(t) + Y_{3}(t)},
\]

(2.12)

where in the second expression we switch to the multi-state notation. If the model is Markov with censoring intensities \( \lambda_i(t) \), \( i = 1, 2, 3 \) from states 1, 2, and 3 then \( dH_3(t) \) does not estimate

\[
dH_3(t) = dA_{34}(t) \left[ \frac{p_3(t)}{p_1(t) + p_2(t) + p_3(t)} \right]
\]

(2.13)

in general, but instead estimates \( dA_{34}(t)P_{3}^{*}(t) \), where \( P_{3}^{*}(t) \) is the probability an individual is in state 3, given that they are in states 1, 2, or 3 (and thus uncensored). The quantity \( dA_{34}(t)P_{3}^{*}(t) \) equals (2.13) only if \( \lambda_1(t) = \lambda_2(t) = \lambda_3(t) \).

Robins (1993), Satten et al. (2001) and others have suggested a way to adjust estimators for adaptive censoring, by identifying internal time-dependent covariates, denoted by \( Z(t) \), with history \( \bar{Z}(t) = \{ Z(u), 0 \leq u < t \} \), such that at time \( t \) the censoring intensity satisfies

\[
\lambda_C(t|Z(t), T \geq t) = \lambda_C(t|\bar{Z}(t)).
\]

They propose the use of “inverse probability of censoring weighted” estimates for survival probabilities and other quantities. In the context of survival times \( T \), let

\[
K_i(t) = \prod_{s \leq t} [1 - d\Lambda_C(s|Z_i(s))]
\]

where \( d\Lambda_C(t|Z_i(t)) = \lambda_C(t|Z_i(t))dt \). Robins (1993) and Satten et al. (2001) consider \( \bar{N}(t) = \sum_{i=1}^{n} I(t_i \leq \min(t, \tau_i))/K_i(t_i-) \) and \( \bar{S}(t) = \sum_{i=1}^{n} I(t \leq \min(t_i, \tau_i))/K_i(t^-) \). They prove that \( E(\bar{N}(t)) = E(\bar{N}^*(t)) \), where \( N^*(t) = \sum_{i=1}^{n} I(t_i \leq t) \), and \( E(\bar{S}(t)) = E(\bar{S}^*(t)) \), where \( \delta^*(t) = \sum_{i=1}^{n} I(t \leq t_i) \). As a result, if \( K_i(t) \) is known, and \( w_1, \ldots, w_L \) denote the \( L \)
unique failure times,
\[
\bar{S}(t) = \prod_{w_k \leq t} \left(1 - \frac{d\hat{N}(w_k)}{\hat{\delta}(w_k)}\right)
\]
(2.14)
is consistent for \(Pr(T \geq t)\). Replacing \(K_i(t)\) with a consistent empirical estimate, \(\hat{K}_i(t)\), gives
\[
\hat{N}(t) = \sum_{i=1}^{n} I(t_i \leq \min(t, \tau_i))/\hat{K}_i(t_i-)
\]
and
\[
\hat{\delta}(t) = \sum_{i=1}^{n} I(t \leq \min(t, \tau_i))/\hat{K}_i(t^-).
\]
\(\delta(t) = \sum_{i=1}^{n} I(t \leq \min(t, \tau_i))\) then with known \(K_i(t)\), Satten et al. (2001) show that
\[
\hat{S}(t) = \prod_{w_k \leq t} \left[1 - \frac{d\hat{N}(w_k)}{\hat{\delta}(w_k)}\right]
\]
is then a consistent estimate of the marginal survivor function, \(S(t) = Pr(T \geq t)\).

In the context of progressive multi-state models such as the one represented in Figure 1, inverse probability of censoring-weighted methods can be used to obtain consistent estimates of the distributions for the time to entry/exit of each state. As a result estimates of the state occupancy probabilities based on (2.8) can be corrected for state-dependent censoring.

This method of inverse probability of censoring-weighted estimation was generalized to deal with multi-state processes in Datta and Satten (2002) where the focus was on marginal transition rates. Let \(s_{i1}, \ldots, s_{ir_i}\) denote the \(r_i\) transition times for subject \(i\). Then let
\[
\tilde{N}_{kk'}(t) = \sum_{r=1}^{r_i} \frac{I(s_{ir} \leq \min(\tau_i, t))dN_{kk'}(s_{ir})}{K_i(s_{ir}-)}
\]
and
\[
\tilde{Y}_{ik}(t) = Y_{ik}(t)I(t \leq \tau_i)/K_i(t^-) .
\]
Replacing \(K_i(t)\) with a consistent estimate gives \(\tilde{N}_{kk'}(t)\) and \(\tilde{Y}_{ik}(t)\), which give
\[
\hat{N}_{kk'}(t) = \sum_{i=1}^{n} I(t \leq \tau_i)\tilde{N}_{kk'}(t)
\]
and
\[
\hat{Y}_{ik}(t) = \sum_{i=1}^{n} I(t \leq \tau_i)Y_{ik}(t) .
\]
These can in turn be used to compute weighted Nelson-Aalen estimates of the integrated partially conditioned transition rates as
\[
\tilde{A}_{kk'}(t) = \int_{0}^{t} I(\tilde{Y}_{ik}(u) > 0)d\tilde{N}_{kk'}(u)/\tilde{Y}_{ik}(u),
\]
(2.15)
and an estimate of the transition probability matrix by (2.10). These give estimates of state occupancy probabilities that are robust to departures from the Markov model when there is adaptive or state-dependent censoring.

The weighted Glasziou-Pepe approach and the weighted Aalen-Johansen approach enable one to adjust for state-dependent censoring in estimating state prevalence functions. In general, however, considerable effort may be required to identify a suitable model for $\lambda_C(t|Z(t))$; see Datta and Satten (2002). If censoring is only state- and time-dependent, then $\lambda_C(t|Z(t)) = \lambda_{JC}(t)$ and adjustments are readily made; we consider this in Section 3.

Instead of modelling the censoring intensity, an alternative approach is to specify intensities for the state transitions, thus rendering the censoring process ignorable. State prevalence functions can then be estimated from this model. Intensity based methods for multi-state processes raise issues of model specification and diagnostic checks are essential to assess fit, because the prevalence estimates may be non-robust to departures from the model. Advantages of this approach include a more thorough understanding of the process of interest, and the ability to use the model for prediction. If interest lies solely in the prevalence functions, however, then censoring-adjusted Markov-based estimation is appealing.

3 An example

To illustrate the methodology and various points discussed in the preceding sections, we consider a randomized clinical trial of adjuvant chemotherapy for breast cancer that was conducted by the International Breast Cancer Study Group (IBCSG). This study investigated the effectiveness of short duration (one month) and long duration (six or seven months) chemotherapy (e.g., see The Ludwig Breast Cancer Study Group 1988, Gelber et al. 1995). A total of 1,229 patients were randomized to treatment: 413 to the short duration treatment and 816 to the long duration treatment. Median follow-up time was about seven years.

These data have been the subject of various quality of life analyses, based on a four state progressive model as displayed in Figure 1. In this case the four states were 1: Toxicity, 2: Toxicity-free and symptom-free, 3: Relapse, and 4: Death. Quality of life utilities for states 1-4, such as $v_1 = 0.5$, $v_2 = 1.0$, $v_3 = 0.5$, $v_4 = 0$, have been used by many authors; Gelber et al. (1995) provide references. We focus here on estimation of the prevalence functions $p_j(t) = P_{ij}(t)$, $j = 1, 2, 3, 4$ for patients in the two treatment groups, but will discuss total quality of life at the end of the section. For the analyses here, we dropped 16 patients for whom one or more state transition times were missing, leaving 411 and 802 subjects in the short and long duration groups, respectively.

Figure 2 shows Kaplan-Meier estimates of the survivor functions $S_j(t)$, $j = 1, 2, 3$ for the times $T_j$ at which the sojourn in state $j$ ends, for the two treatment groups. The

Figure 3: Prevalence estimates for states 2 and 3 for the long duration chemotherapy group.
prevalence functions can be estimated from (2.8); these estimates are apparent from the figure. Figure 3 shows prevalence estimate $\hat{P}_{12}(t)$ and $\hat{P}_{13}(t)$ based on both (2.8) and the Markov (Aalen-Johansen) estimator (2.10), for the long duration group. The two estimates for $P_{12}(t)$ are virtually identical, but those for $P_{13}(t)$ differ substantially. Pointwise .95 confidence limits for the Glasziou-Pepe estimator (2.8), obtained via 500 nonparametric bootstrap samples, are also shown. Each bootstrap sample was a sample of 802 subjects, drawn with replacement from the 802 long duration chemotherapy subjects. The confidence limits are the estimated prevalence plus or minus 1.96 standard errors, which were estimated from the 500 bootstrap samples.

As discussed in Section 2, the estimates represented in Figure 3 are robust, provided that the censoring mechanism is completely independent of the multi-state process. The Markov estimate is also valid under more general independent censoring (Andersen et al. 1993) if the multi-state process is actually Markov. However, the estimates may be
biased if these assumptions are not met. It is therefore advisable to assess the censoring process and also the state transition intensities.

An examination of censoring suggests that it is not completely independent of the multi-state disease process. In particular, the censoring intensity at time $t$ on study differs according to whether an individual is in state 1, 2 or 3 at time $t$. First, all individuals spend only a short time (9 months or less) in state 1, and no one in the study was censored while in state 1. Figure 5 shows estimated cumulative censoring intensities $\hat{\Lambda}_{2C}(t)$ and $\hat{\Lambda}_{3C}(t)$ for the Markov model portrayed in Figure 4, where the state $C$ stands for “censored”, or withdrawn from the study. Because no individuals were censored from state 2 until well after 12 months on study, and because there were only a very few subjects who progressed to state 3 before 12 months, we have shown the Nelson-Aalen estimates $\hat{\Lambda}_{2C}(t) - \hat{\Lambda}_{2C}(12)$ and $\hat{\Lambda}_{3C}(t) - \hat{\Lambda}_{3C}(12)$ in the figure. Two features are apparent: (1) the censoring intensities from states 2 and 3 are very different for $t \leq 60$ months, and (2) up to about $t = 48$ months the censoring intensity for state 3 is substantially higher for the long duration group than for the short duration group. These features suggest that some individuals were withdrawn from the study after relapse and that this was more pronounced in the long duration chemotherapy group.

Diagnostic checks on the Markov model, for which the transition intensities $\lambda_{12}(t)$, $\lambda_{23}(t)$ and $\lambda_{34}(t)$ in Figure 4 are functions of time on study only, did not show serious departures from the model for either the short or long duration groups. These checks included the introduction of terms in multiplicative models for $\lambda_{i,i+1}(t | Y(t))$ that
Cumulative processes related to event histories

represented time since entry to the current state, and sojourn times in previous states. This suggests that the Markov prevalence estimates should be fairly robust to the state-dependent censoring. As a further check, we used censoring-related weights as defined in (2.14) and (2.15), with the censoring intensity $d\Lambda_C(s|Z_i(s)) = d\Lambda_C(s)Y_i(s)$ at time $s$ depending on the state occupied. This made very little difference in the Markov estimates for either $P_{12}(t)$ or $P_{13}(t)$. Interestingly, the use of weighted Kaplan-Meier estimation for the Glasziou-Pepe prevalence estimates based on (2.8) also made very little difference, even though the unweighted estimates are affected by state-dependent censoring. The overestimation of state 3 prevalences in Figure 3 (and in Figure 6 below) is as suggested by a comparison of (2.13) with $dA_{34}(t)P^*_3(t)$. In the setting here, $P^*_3(t)$ underestimates the term in square brackets in (2.13), so the estimate (2.9) for $j = 3$ is biased up, as is the estimate of $p_3(t)$ from (2.8).

The transition intensities from states 3 to 4 might be expected to depend on time in state 3 (i.e. time since relapse). Although the checks on the Markov model did not indicate any such dependence, we also fitted a model for which

$$\lambda_{34}(t|Y(t)) = \lambda_0(t - t_2)e^{\beta_2}. \quad (3.1)$$

This model gave a reasonably satisfactory fit, especially for the short duration chemotherapy group. The effect of $t_2$ in (3.1) was highly significant, with $\hat{\beta_2} > 0$ indicating a negative association between time spent in the toxicity and toxicity-free states, and the relapse state. This effect is sometimes seen in other cancer treatment studies, where patients with longer times to relapse tend to have somewhat shorter survival after relapse. Our preference here is for the simpler Markov model, but we note that if (3.1) is adopted the prevalence estimate for $P_{13}(t)$ becomes

$$\hat{P}_{13}(t) = \int_0^t \exp[-e^{\hat{\beta_2}u}\hat{\lambda}_0(t - u)](-dS_2(u)). \quad (3.2)$$

Figure 6 shows this estimate along with the Gelber-Pepe and Markov estimates for the short duration group. We see that the new estimate falls substantially below the other two. There is no obvious explanation for this, except that prevalence estimates from semi-Markov models appear to be quite non-robust to model departures (e.g. Couper and Pepe 1997). Another possibility that would also affect the Markov estimates is that some persons were withdrawn from the study because of factors related to future prognosis. This would render the censoring non-independent.

Quality of life (QOL) utilities used by Glasziou et al. (1990) and others for this study were $v_1 = 0.1$, $v_2 = 0.5$, $v_3 = 0.1$. Because the Glasziou-Pepe and Markov prevalence estimates differed substantially only for the low-utility state 3, the corresponding estimates of cumulative quality of life, which from (1.5) are

$$\hat{\mu}(t) = \sum_{j=1}^3 v_j \int_0^t \hat{p}_j(u)du, \quad (3.3)$$
do not differ much. In particular, the estimated mean QOL $\mu(t)$ at $t = 84$ months (as discussed by previous authors) for the long duration group is 29.29 (Markov estimate) or 29.54 (Glasziou-Pepe estimate), with standard errors estimated by 500 bootstrap samples of about 0.43. For the short duration group the corresponding estimates for $\mu(84)$ are 26.20 and 26.35, with standard errors of about 0.65.

4 Discussion

Multi-state models often provide an effective way to deal with cumulative cost or quality processes. As indicated, robust estimation of state prevalence functions is possible in many settings; this provides estimates of expected cumulative cost in the settings discussed here. However, the development of full probabilistic models for a multi-state process has the added advantages of providing (in conjunction with the cost model) estimates of the distribution of costs, prediction, and ways of dealing with incomplete data due to intermittent observation or selective sampling of subjects.

There are several areas that deserve further attention. One concerns efficiency and robustness trade-offs among the methods of prevalence function and expected cost estimation discussed in Sections 2 and 3. Limited simulation studies carried out by us and others (e.g. Couper and Pepe 1997, Datta and Satten 2002) for specific multi-state models suggest that the Markov (Aalen-Johansen) estimates are both more efficient and more robust to adaptive censoring than the Glasziou-Pepe estimates. They also suggest that estimates based on semi-Markov models are highly susceptible to departures from the model even under random censoring. Interestingly, the use of censoring-based weighting as described in Section 2.3 seems to have a relatively small effect in many situations involving adaptive or state-dependent censoring. Further study is needed, but it may be that censoring has to be highly adaptive for the weighting to make much difference. In practice there is, of course, the problem of having to model the censoring process in order to produce weights, and the effects of model misspecification here have not been investigated.

It would also be worthwhile to study the estimation of cost distributions, and variance estimation and confidence interval procedures for cost distribution characteristics. Nonparametric bootstrap methods based on resampling individual data histories seem to the most feasible approach at present.

In many applications it may not be feasible to define states in such a way that the cost processes are linear with rates $v_j$, or even deterministic, given the state occupied. A more general cost process that has some degree of tractability is that the cumulative cost up to a duration $s$ for a sojourn in state $j$ is $v_j s + Z_j(s)$, where $\{Z_j(s), \ s \geq 0\}$ is a stochastic process with independent increments. It seems important for tractability and interpretability that we define states so that (1.7) holds, that is, so that state transition intensities are independent of cost history, given the multi-state history. In some cases
Cumulative processes related to event histories

we may want to stratify individuals or add covariates to the multi-state process in order to achieve this.

**Resum**

Els beneficis o costos acumulats al llarg del temps per als individus són aspectes d’interès en molts processos sobre la història dels esdeveniments. Exemples familiars inclouen el cost mèdic per a persones amb una malaltia crònica, els pagaments a les persones assegurades durant els períodes de discapacitat, i la qualitat de vida usada de vegades en l’avaluació del tractament en pacients terminals. Usarem aquí el terme cost per a referir-nos al cost o a d’altres mesures acumulades. Hi ha dos escenaris importants: (i) aquell en què els costos estan associats amb l’ocurrència de certs esdeveniments, i en aquests el cost total s’acumula com una funció esglaonada, i (ii) aquell en què els individus es mouen entre diferents estats al llarg del temps, amb un cost que s’acumula a una taxa constant determinada per l’estat que s’ocupa. En ambdós casos, acostuma a definir-se una variable aleatòria T que representa la duració del procés que genera els costos. Considerarem aquí l’estimació del cost mitjà acumulat al llarg d’un període d’interès usant mètodes basats en aspectes marginals dels processos i models d’intensitat. Es discuteix la robustesa dels mateixos per esquemes de censurament adaptatiu en el context de mètodes multi-estat. Els mètodes s’il·lustren amb dades d’un estudi de qualitat de vida amb pacients amb càncer de pit.
